## Introduction

This is my coursework for COMP6411, on the Haskell programming language. Inside this part we discuss the different powers of the programming language, the flexibilities, and other shortcomings.

The application in question is a fractal generator. In order to provide a solution to this problem, we need to decide on two things:

1. Decide on what fractal algorithm we will choose
2. Decide on how we will display the outcome

This clearly separates this case study into two parts. One part is to define a library that we can call in order to generate images. The other part is to implement the actual fractal algorithm, and auxiliary functions.

## Language Exploration

In this section we show aspects of the programming language. We show the typing system and signatures, functions, higher order functions, and recursive functions. We also show how some basic *Haskell* applications or modules are written and used.

### 2.1 Types

We discuss some basic *Haskell* types in this section. The operations listed were what were deemed useful for the case study. There exist many other possible operations that a user of the language can use, and it is left for the user for exploration.

**Lists** are used by enclosing elements between square brackets. For example, `[1, 10, 2, 4]` is a valid list. Lists are required to contain elements of the same type however. For example `[1, 2.0, "cat"]` would raise compilation issues. We are provided with the *head* and *tail* operations in order to manipulate lists. We are also given some very useful operations called *take* and *drop* which return the first *n* specified elements, or return the tail after *n* elements respectively. Mapping functionality exists, so applying lambdas on lists is also possible. Another useful operator is the `!!` infix operator, which returns us an element at a given index. Some sample output is provided in Listing 1. There exists a *cons* operator, and in *Haskell* it is the colon.

```

1 Prelude> [1,2,3,4]
2 [1,2,3,4]
3 Prelude> [1,2,3,"cat"]
4
5 <interactive>:11:2:
6   No instance for (Num [Char]) arising from the literal '1'
7   Possible fix: add an instance declaration for (Num [Char])
8   In the expression: 1
9   In the expression: [1, 2, 3, "cat"]
10  In an equation for 'it': it = [1, 2, 3, ....]
11
12 Prelude> head [1,2,3,4]
13 1
14 Prelude> tail [1,2,3,4]
15 [2,3,4]
16 Prelude> take 2 [1,2,3,4]
17 [1,2]
```

```

18 Prelude> drop 1 [1,2,3,4]
19 [2,3,4]
20 Prelude> [1,2,3,4] !! 0
21 1
22 Prelude> [1,2,3,4] !! 2
23 3
24 Prelude> 12 : [1, 2, 3]
25 [12,1,2,3]
26 Prelude> "mommy cat" : ["kitten", "kitten", "kitten", "kitten"]
27 ["mommy cat", "kitten", "kitten", "kitten", "kitten"]

```

Listing 1: Simple List Operations

Another interesting feature in the lists of *Haskell* is that we are able to define ranges, and evaluate them lazily. We use two periods between two numbers in order to achieve this. The following are valid ranges: `[1..100]`, `[0.5..0.9]`. If we omit the rightmost number, then we tell *Haskell* that it is a list that goes on to infinity. This is legal due to the lazy nature.

Another very useful aspect of the language is that we can use *list comprehensions*. List comprehensions and lazy evaluation add to the power of the language dramatically.

**Strings** can be specified by using the quotation marks. For example “My kitten is cute” is a valid string. Strings however are lists of characters. They have been aliased as the type *String*. So in fact, we can say `String = [Char]`. It follows that any operation that we can perform on a list as previously stated, is possible to be used in Strings as well. For example, the head of the string “hello” would return the character ‘h’, and the tail would return “ello”. In this respect, we can also map functions onto strings. Listing 2.

```

1 Prelude> :t "hello"
2 "hello" :: [Char]
3 Prelude> ["hello", "there"]
4 ["hello", "there"]
5 Prelude> :t ["hello", "there"]
6 ["hello", "there"] :: [[Char]]
7 Prelude> head "hello"
8 'h'
9 Prelude> tail "hello"
10 "ello"
11 Prelude> Data.Char.toUpper 'a'
12 'A'
13 Prelude> map Data.Char.toUpper "hello there"
14 "HELLO THERE"
15 Prelude> take 4 "hello"
16 "hell"
17 Prelude> 's' : take 4 "hello"
18 "shell"

```

Listing 2: Strings are Character Lists (Don’t believe what they told you)

**Others** We also have other primitives such as Booleans, Integers, Doubles, and tuples in our disposal. Tuples are defined by using parentheses, and separating its types with commas: `(String, Int, Double)` is a valid tuple.

## 2.2 Recursion

Recursion is possible in *Haskell*. Similarly to *Prolog* we are given to separate the base cases from the body of the function. The recursive cases remain in the body of said function. Therefore, the base cases are evaluated in the order they appear in. For example consider the code in Listing 3.

```
1
2 module MyTest where
3
4 mycase 1 = 10
5 mycase 2 = 20
6 mycase 3 = 30
```

Listing 3: Cases using argument values

If we executed *mycase 1* we would return the value '10'. If we executed *mycase 2* we would return the value '20'. If we executed this function with the argument value '4', then we would get an error.

Now provided the mechanism on how to define base cases, let us take a look how a factorial implementation would look like in *Haskell*. Listing 4 shows us this.

```
1 module Factorial(myfactorial) where
2
3 myfactorial :: Int -> Int
4 myfactorial n =
5   case n > -1 of
6     True  -> factorialback n
7     False -> error "Please supply positive integers"
8
9 factorialback :: Int -> Int
10 factorialback 0 = 1
11 factorialback n = n * factorialback (n - 1)
```

Listing 4: Factorial in Haskell

Listing 5 shows us some example usage.

```
1 *Factorial> myfactorial 3
2 6
3 *Factorial> myfactorial 10
4 3628800
5 *Factorial> myfactorial 14
6 87178291200
7 *Factorial> myfactorial (-3)
8 *** Exception: Please supply positive integers
```

Listing 5: Factorial Output

One might notice that there is no safeguard for giving negative integers. This is prevented actually on compile time.

## 2.3 Visibility & Signatures

In comparison to other languages such as *C*, *C++*, *OCaml*, Haskell does not define its interfaces to its modules in a separate file - there is no separation between specification and implementation. In order to achieve visibility, we need to specify the function names which we want to expose between brackets after the module name. We can see such an example in Listing 6.

Haskell is a strong typed language. This adds to the compiler's task at seeing if the user of the language is trying to do something erroneous. As such, *Haskell* does not support casting, or other features that might cause problems during runtime. The idea is to catch as many bugs as possible during compile time, using the type system.

```
1 -- @author Simon Symeonidis
2 module MyModule(toStrList) where
3
4 ...
```

Listing 6: Exposing Functions in a Module

Signatures exist in Haskell. They can be thought of as prototype functions in *C/C++*. A Haskell signature is similar to those of *OCaml*. We need to specify a name, then add a double colon, and separate it with its type signature which contains the return type as the last type. Here is an example:

*functionName* :: *<signature>*

We can see a more implemented example in Listing 7. We can observe the function name *toStrList*, on its right the separator `::`, and then the type signature `[Int] -> [String]`. Recall that we said that the last type is the return type. Therefore this makes us understand that all the types right before the rightmost are the input parameters. So in the case of *toStrList*, we understand that this function takes in a List of integers, and returns a list of strings.

```
1 -- @author Simon Symeonidis
2 module MyModule(toStrList) where
3
4 -- | Example where we convert an integer list to a string list. The signature
5 -- is on the first line bellow. The second line below it uses the map function
6 -- performing 'show' on each element which converts it to a String. We return
7 -- a list of strings, as specified by the signature.
8 toStrList :: [Int] -> [String]
9 toStrList lst = map show lst
10
11 -- Example usage:
12 -- [psyomn@aeolus misc 0]$ ghci MyModule.hs
13 -- GHCi, version 7.6.3: http://www.haskell.org/ghc/  :? for help
14 -- Loading package ghc-prim ... linking ... done.
15 -- Loading package integer-gmp ... linking ... done.
16 -- Loading package base ... linking ... done.
17 -- [1 of 1] Compiling MyModule          ( MyModule.hs, interpreted )
18 -- Ok, modules loaded: MyModule.
19 -- *MyModule> toStrList [1,2,3,4,12313,123123123,231]
20 -- ["1","2","3","4","12313","123123123","231"]
```

Listing 7: Example Module with Function

### 2.3.1 Generics

Generics can be thought of like templates in *C/C++* or *Java*. This means that the possibility of reusing a function with many types is possible. Let us revisit the example where we were converting integers into lists (Listing 7). This is a nice function, but it only works for *Integer* input. What if we wanted to use it for various data types? This is where the use of generics are deemed useful. A generic is defined by a lowercase character. So if we want a list of ‘things’, whatever they may be, we denote that this way:  $[a]$ . Extending on the previous example, we first need to change the type signature. Since we want any type and not only Integers, we need to replace the parameter. So the signature now becomes:  $[a] \rightarrow [String]$ .

However there is one last thing that we need to take care about our generic type ‘a’. If we wish for the possibility of converting each element ‘a’ into a string, we need to impose the type constraint *Show*. This requires that any type we pass to this new function should have behavior defined for ‘show’ (which is similar to *toString* functions in other programming languages). The signature now becomes:  $(Show\ a) \Rightarrow [a] \rightarrow [String]$ .

As you might have inferred, constraints are imposed by writing them at the left-most of the type signature. If more constraints were to be added, you would separate them by commas. So for example if we also wanted the generic type ‘a’ to be constrained by ‘Ord’ (if something is order-able), we would change the constraint to:  $(Show\ a,\ Ord\ a)$ . Listing 8 shows the generic implementation of the list to string function, and 9 shows the output when providing different lists of different element types.

```
1 module MyModuleGeneric (genToStr) where
2
3 genToStr :: (Show a) => [a] -> [String]
4 genToStr things = map show things
```

Listing 8: Generic toStr

```
1 *MyModuleGeneric> genToStr [1,2,3,4]
2 ["1","2","3","4"]
3 *MyModuleGeneric> genToStr [1.0, 2.0, 3.0]
4 ["1.0","2.0","3.0"]
5 *MyModuleGeneric> genToStr[True, False, True, True]
6 ["True","False","True","True"]
```

Listing 9: Generic Output

### 2.3.2 Higher Order Functions

Higher order functions are supported in *Haskell*. One thing to note is how to express them inside the function you are defining, that will use that function. The rest is not too hard to get working. For the sake of this example we will be implementing our own filter. (Recall that a filter tests the list’s elements against a predicate, and are added to the new list if they satisfy said predicate).

First we need to define the signature. We know there are two inputs: the predicate, and the list to test it against. We expect a list, empty or non-empty after the operation has completed. We can first piece together the following:  $function \rightarrow [a] \rightarrow [a]$ . That is we expect after passing the function and a list of elements type ‘a’, to return a list of type element ‘a’.

Next we need to define the function in more detail. To specify a higher order function we need to encase the signature in parentheses. Our predicate gets an element ‘a’, and returns a ‘Boolean’. Therefore the predicate inside the function we are trying to define looks like  $(a \rightarrow Bool)$ .

Putting the signature together we have the following:  $myfilter :: (a \rightarrow Bool) \rightarrow [a] \rightarrow [a]$ . The implementation uses recursion in order to build the list, depending on whether the predicate is satisfied or not. Listing 10 shows the final implementation of the function.

```
1 module MyFilter(myfilter) where
2
3 myfilter :: (a -> Bool) -> [a] -> [a]
4 myfilter _ [] = []
5 myfilter f (x:xs) =
6   case f x of
7     True  -> x : myfilter f xs
8     False -> myfilter f xs
```

Listing 10: Our Own Filter

You may notice the underscore in the base case of this function. That is an anonymous variable. Since we do not care about the predicate in the base case we are free to omit it.

## 2.4 Defining your own Infix Operators

You can also define your own infix operators. This is a useful feature in the programming language. Here is an example where we used this in order to implement the ‘99 bottles of beer’ problem. Notice the backticks on ‘bottles’ in Listing 11.

```
1 {- Using the infix operator, trying to make more concise code.
2   @author Simon Symeonidis -}
3
4 module Main(main) where
5
6 import Text.Printf
7
8 bottlesPlurals :: Int -> String
9 bottlesPlurals x = case x == 1 of
10   True  -> "bottle"
11   False -> "bottles"
12
13 bottles :: Int -> String -> String
14 0 'bottles' str = "No more " ++ (bottlesPlurals 0) ++ str
15 x 'bottles' str = (show x) ++ " " ++ (bottlesPlurals x) ++ str
16
17 makeSong :: Int -> String
18 makeSong 0 = ""
19 makeSong x =
20   x 'bottles' " of beer on the wall, " ++
21   x 'bottles' " of beer. " ++ "Take one down and pass it around, " ++
22   (x - 1) 'bottles' " of beer on the wall. " ++ makeSong (x - 1)
23
24 main = do
25   printf $ makeSong 99
```

Listing 11: 99 Bottles of Beer in Haskell

## Problem Dissection

For this case study, I decided to write up a fractal generator. This required two steps. Writing a small library for outputting images, and writing the fractal mathematical formulas.

### 3.1 Writing the Image Library

I was looking for a specification of an image format that would not be too hard to implement due to the time constraint I had for this project. Therefore the ideal format for my application would be something that could be represented as text. Apart from being really easy to implement, it would be easy to debug as well, since the output would be text files.

Searching on the Internet I finally stumbled upon the *PPM* format for images. There are two versions of the format one may implement. This is read by the image viewer on the file headers. If you specify P6, then it expects to read the image data as raw bits. However if you specify P3, you can enter the image data by 3-tuples of pixels (where the tuple contains the luminosity of the Red, Green, and Blue colors). More information on the file format can be read about here: <http://netpbm.sourceforge.net/doc/ppm.html>.

The best approach for this was to define a data type *Pixel* which contained these three colors. Then we could define auxiliary functions to modify the information, or read it. Such behavior is found in Listing 17. Notice first the two types: *Pixel*, and *PPMImage*. The *pixel* defines another 3 elements which will be placeholders for the RGB colors, and *PPMImage*, is the whole image - the header information, dimensions and image data included. Using these two types, we build the foundations for completing the rest of the application.

We can notice some of the auxiliary functions *redOf*, *blueOf*, *greenOf*. Those are used in order to extract the luminosity of the pixels. Notice how the anonymous variables are used in order to only get the data that we want for each.

The next important functions are *makeRow*, *makeImage*, and *makeImageData*. These functions help us create the image in question. The *makeRow* function creates a row of pixels. This function is used 'n' times in the back-end of the *makeImage* function in order to give height to the image. We have yet more auxiliary functions such as *makeWhiteImage*, *makeGreenImage*, *makeBlackImage*, etc which provide us shorthands to create images of x, y dimensions. The *makeBlackImage* function is used later in order to provide a background to the fractal.

Last but not least are the string conversion functions that return the image as a string. This is important because as previously stated, we wish to export the image into a text format that is viewable as a picture by an image viewer.

First we need to take care of the finely grained issue - converting a single pixel into a tuple of three numbers as a string. This is observed in the *pixelString* function in Listing 17. Then we define a recursive function that goes through a whole row in an image, and converts it into a string - namely *outputRow*. Finally we define one last function to take care of output for a whole image, *imageString*, *imageStringBackend*. This concludes the requirements of having a library that is able to generate our images.

### 3.2 Julia Sets and Fractal Implementation

The next important listing to look at is 16. We wish to investigate Julia sets using the quadratic polynomial below. The quadratic polynomial was obtained from here: [http://en.wikipedia.org/wiki/Mandelbrot\\_set](http://en.wikipedia.org/wiki/Mandelbrot_set). The 'z' values are always replaced by the previous value that was obtained calculating the function with constant 'c'. Constant 'c' is a arbitrary imaginary number that is supplied.

$$z_{n+1} = z_n^2 + c$$

Now there are two things that we need to consider: the ranges that the set is defined inside, and the range of the image dimensions. That is, we need to super impose the dimensions of the cartesian plane where the fractal is defined, on an array representing an image. Therefore, for each array index that we have in our image, we stretch the range of the cartesian plane over it. This means that each index adds a small fraction to the dimension. If for example we had an image of size 2000 pixels wide, and our cartesian plane was

from the range -2 to 2, then for each pixel, we need to add a small amount that is calculated in the ‘grain’ function in Listing 16. This function translates to the following:

$$grain = \frac{abs(minv) + abs(maxv)}{distance_{minmax}}$$

A list comprehension is used in order to populate the array with these values. The list comprehension can be spotted inside the function *makePlane*.

Another aspect to take into consideration is that we need to calculate values using imaginary numbers. To do this, we import the complex numbers in Haskell. We can define imaginary numbers like this: *1.0 :+ 2.0*, where the left part is the real part, and the right part is the imaginary part. Operators are overloaded in order to perform calculations if needed.

The plane is populated with these imaginary values. The real parts are affected from left to right, by the grains as stated (so for each succeeding pixel from left to right, we add ‘n’ times this grain). The imaginary parts are affected from top to bottom (using the +y to -y values for the grain formula).

Finally we need to apply the polynomial function *z* recursively on a pixel’s imaginary values. The formula is repeatedly called, using the previous output as its input. Each time, we test the Euclidean distance from the center of the plane, to the new coordinate. The Euclidean distance uses the raw magnitudes of the complex numbers for the ‘x’ and ‘y’ inputs.

$$euclidean = \sqrt{abs(magnitude_{real})^2 + abs(magnitude_{imaginary})^2}$$

We keep track at how many times we applied the *z* function until we got a value more than 2, when calculating its Euclidean distance. If it’s greater than 2, then it means that it has escaped the plane of interest and that that point does not belong to the Julia set. However, if it takes a considerable amount of iterations in order to escape this boundary, we note this point as belonging to the Julia set. The points belonging to the Julia set are what make up the visible part of the fractal on pictures. Also, the intensity of that particular point’s color is determined by the amount of iterations required in order for it to escape (or remain) in the plane.

### 3.3 Image Output

Here are some fractals, generated by the program, providing different constants ‘c’. Note that the colors were edited after the output, for facilitating printing.
